### Abstract

We consider a model of recommendation systems, where each member from a given set of *players* has a binary preference to each element in a given set of *objects*: intuitively, each player either likes or dislikes each object. However, the players do not know their preferences. To find his preference of an object, a player may *probe* it, but each probe incurs unit cost. The goal of the players is to learn their complete preference vector (approximately) while incurring minimal cost. This is possible if many players have similar preference vectors: such a set of players with similar “taste” may split the cost of probing all objects among them, and share the results of their probes by posting them on a public *billboard*. The problem is that players do not know a priori whose taste is close to theirs. In this paper we present a distributed randomized peer-to-peer algorithm in which each player outputs a vector which is close to the best possible ap-

proximation of the player’s real preference vector after a polylogarithmic number of rounds. The algorithm works under adversarial preferences. Previous algorithms either made severely limiting assumptions on the structure of the preference vectors, or had polynomial overhead.

Algorithms, Theory.

### Keywords

recommendation systems, collaborative filtering, randomized algorithms, electronic commerce, probes, billboard.

## 1. Introduction

Information fusion, recommendation systems, belief propagation networks, collaborative filtering, distributed agent learning are all classical subfields of Computer Science and Artificial Intelligence. These sub-fields attempt to improve efficiency of multiple agents (human or mechanical), which are trying to leverage past experience of others in spite of significant diversity or uncertainty in their perception of the world. There are many reasons for such diversity, e.g., people may have different taste (for books, movies, food, etc.), sensors may experience different reception due to different location, some eBay users may be dishonest, links on websites of different companies point to different suppliers preferred by these companies, etc. Even when no inherent diversity appears to exist, various time-variable factors (such as noise, weather, mood) may create diversity as a side effect.

There is a tremendous amount of work in AI and CS on modeling such diversity (e.g., [10, 16, 13]); in fact, some conferences are dedicated exclusively to this topic. Intuitively, it seems that arbitrary diversity is unmanageable,

and strong assumption need to be made in order come up with algorithms algorithmic tools. All existing approaches restrict diversity somehow, e.g., by assuming that user profiles are a linear combination of a few “major types.” These assumptions are hard to justify, but superficially they appear unavoidable. In this paper, perhaps counter-intuitively, we present novel algorithmic tools that show that effective (near optimal) collaboration by cooperative agents is possible even with unrestricted diversity.

Many commercial systems (e.g., Amazon, eBay, Epinion) are based on explicit or implicit notion of trust and user preferences. Such preferences may be represented by a matrix where rows represent agents, and columns represent objects. Each entry  $(i, j)$  represents the (unknown) opinion of agent  $i$  about object  $j$ . One of the fundamental tasks of a recommendation system (e.g., an advertiser like Google) is to reconstruct the full matrix.

The challenge in these systems is how to take advantage of the existence of users with related opinions: Intuitively, a set of users with similar preferences should be able to collaborate, implicitly or explicitly, by sharing the load of searching the object space and sharing the results of their probes. To facilitate information sharing, it is assumed that the system maintains a shared *billboard*, similar, for example, to the eBay ranking matrix, where users post the results of their probes. The difficulty is that users do not know whose grades to adopt and that tastes may differ to some degree even between potential collaborators. Below, we describe two basic models for recommendation systems: interactive and non-interactive.

**Interactive recommendation system.** In this model, the basic action available to algorithms is to reveal a grade the algorithm chooses, but such an action incurs cost [6, 4]. Revealing a grade models the process of a user testing a product, called *probing*. For example, consider advertisement placement. Probing takes place each time the advertiser provides a user with an ad for some product: if the user clicks on this ad, the appropriate matrix entry is set to 1, and if the user does not click, it is set to 0. In any case, the matrix entry is revealed. The task is to reconstruct, for each user, his preference vector, namely his row in the matrix (e.g., so that the advertiser can learn what type does the user belong to). We call such model an *interactive* recommendation system. We note that that many other scenarios, for example tracking dynamic environment by unreliable sensors, or estimating Internet latencies in a peer-to-peer networks [1] fall under this “interactive” framework.

**Non-interactive recommendation system.** This model received much attention, e.g., [12, 11]. Intuitively, while the essence of algorithms for the interactive model is *how to sample*, the essence of algorithms for non-interactive model is *how to interpret* prior sampling. Some assumptions must be made about the known samples in the non-interactive model (on top of the assumptions about the preferences). Typically, it is assumed that the matrix is generated by a low-entropy random process, and that the given probe results are generated by some probability distribution which reflects the users’ preferences.

## 1.1 Problem Statement and Results

In this paper we focus on the interactive model, and present a solution with polylogarithmic cost to interactive recommendation systems that finds all preferences with precision comparable to the best possible for the given probing budget, while making *no assumptions* on user preferences. To date, the best known algorithm in this case had polynomial overhead.

**Statement of the problem.** There are  $n$  players and  $m$  objects; each player has an unknown 0/1 grade for each object. The algorithm proceeds in parallel rounds: in each round, each player reads the shared billboard, probes one object, and writes the result on the billboard. The task of the algorithm is for each player to output a vector as close as possible to that player’s original preference vector (under the Hamming distance metric). We formalize the problem as implementing the following input-output relation.

DEFINITION 1.1 (PROBLEM *Find\_Preferences*). Let  $\text{dist}(x, y)$  denote the Hamming distance between  $x$  and  $y$ .

**Input:** A set  $\mathcal{P}$  of  $n$  players, and a vector  $v(p) \in \{0, 1\}^m$  for each player  $p$ .

**Output:** Each player  $p$  outputs an estimate  $w(p) \in \{0, 1\}^m$  minimizing  $\text{dist}(w(p), v(p))$ .

We note that vector  $v(p)$  can be accessed only by player  $p$ , but  $w(p)$  is accessible to all players.

**Evaluating the algorithms.** Intuitively, our goal is as follows. Call a set of players with similar preferences a virtual community (for some measure of similarity). We would like to show that even in the worst case, players who are members of a sufficiently large virtual community need only a small number of samples to reconstruct (approximately) all their preferences. Obviously, the larger is the community we are considering, the more leverage we get from other members of that community, and thus preference reconstruction for this community is faster. On the other hand, the larger is the community, the larger are internal disagreements between members of the community, and the larger is the error. Our approach is that the probing budget defines the size of the community. For example, linear probing budget means that the player can “go it alone,” and constant (or poly-logarithmic) probing budget means that the player must leverage probes of a large community. Naturally, it is best to pick the tightest (smallest radius) community of the required size. This could have been easily accomplished if each player had access to an oracle that produces a list of players in decreasing similarity of taste, but building such an oracle is, essentially, the task we wish to accomplish. In fact, our algorithm can continuously reconstructs all such sub-communities in parallel, refining clusterings on-the-fly, as time goes on and probing budget is increasing.

What is the best possible output for a given probing budget, i.e., number of probing rounds? Consider first an ideal situation: If all players had *identical* preference vectors, then by dividing the workload equally, all of them can output perfect results in  $O(m/n)$  time units.

More generally, if the disparity (i.e., Hamming distance) between all preference vectors were bounded by some known value  $D$ , then it can be shown that the players can output a vector with  $O(D)$  errors within  $O(m/n)$  time, and then reach full accuracy after time of  $m$ . The latter case corresponds to the following scenario. There exists a subset of players  $P^*$  of cardinality  $n^*$  and internal disparity  $d^*$ . Imagine that these players are perfectly coordinated (in particular, each of them knows the identities of all members in the set), and their common goal is to find their preference vectors as efficiently as possible. The best one could hope for in general is that they can reach disparity of  $O(d^*)$  within  $\tau = m/n^*$  rounds. This consideration leads us to define the following concept. Given a time bound  $\tau$ , and a set of players  $P^*$ , we define the *set stretch* of  $P^*$  as the ratio between the maximal current inaccuracy of a player in  $P^*$  and the diameter of the set of preference vectors of  $P^*$  (using the Hamming distance measure).

More formally, given vectors of equal length, let  $\text{dist}(x, y)$  denote the number of coordinates they differ in (i.e., the Hamming distance between them). Recall that for a player  $p$ ,  $v(p)$  denotes his input vector and  $w(p)$  denotes his output vector. Now, for an arbitrary subset  $P^* \subset \mathcal{P}$ , define

$$\begin{aligned} D(P^*) &\stackrel{\text{def}}{=} \max \{ \text{dist}(v(p), v(q)) \mid p, q \in P^* \} && \text{diameter} \\ \Delta^t(P^*) &\stackrel{\text{def}}{=} \max \{ \text{dist}(w^t(p), v(p)) \mid p \in P^* \} && \text{discrepancy} \\ \rho^t(P^*) &\stackrel{\text{def}}{=} \frac{\Delta^t(P^*)}{D(P^*)} && \text{stretch} \end{aligned}$$

Using the definition of stretch, we state our result.

**THEOREM 1.1 (MAIN RESULT).** *Suppose that  $m = \Omega(n)$ . Let  $P^*$  be any set of players with  $|P^*| = \Omega(n)$ . Then there exists a distributed algorithm such that with probability  $1 - n^{-\Omega(1)}$ , after  $\log^{O(1)} n$  rounds the output of each player in  $P^*$  has constant stretch, i.e.,  $\rho(P^*) = O(1)$ .*

Intuitively, we show that users can predict their preferences for objects they never tried, with confidence that grows with the number of probes executed. The absolute quality of the results depends on how esoteric are the preferences of the user, but constant relative quality can be attained in polylogarithmic time. We note that previous results either made strong assumptions about the input, or forced polynomial cost on all or some users.

**Our techniques and paper organization.** We present our solution in increasing order of complexity.

Algorithm `ZERO_RADIUS`, described in Section 3.1, solves the problem for the special case of communities of users with identical preferences. This algorithm and its proof are quite simple; it is a modification of work published in [3]. In Section 4 we present Algorithm `SMALL_RADIUS`, which uses `ZERO_RADIUS` as a subroutine. Algorithm `SMALL_RADIUS` works for any distribution of the preference vectors, but the probing cost in `SMALL_RADIUS` is polynomial in the diameter of the collaborating set. This property makes `SMALL_RADIUS` suitable for the case where many users have close preferences.

We note that straightforward recursion does not work, because (similarly to metric embedding problems) the error grows exponentially with the depth of the recursion. The crux to the efficiency of this algorithm is a non-trivial combinatorial result that we prove in Lemma 4.1. In Section 5, we present Algorithm `LARGE_RADIUS`, which uses both `SMALL_RADIUS` and `ZERO_RADIUS` as subroutines, and brings down probing cost to poly-logarithmic in the diameter of the collaborating set. It reduces general instances to the zero- and low-diameter case, by first partitioning the object set and then clustering the subsets. All the above algorithms assume that the size and diameter of the collaborating set are known; this assumption is removed in Section 6. Some related work is surveyed in Section 2, and the high-level algorithm with some basic building blocks are described in Section 3.

## 2. Related work

**Interactive model.** Our paper essentially generalizes and improves much of the vast amount of the existing work on multi-agent learning and interactive collaborative filtering. The first algorithmic theory approach is due to Drineas et al. [6], who defined the model we use in this paper. The goal in [6] is to provide a single good recommendation to each user, but the algorithm in fact reproduces the complete preferences of most users. The basic idea is to adapt the SVD technique to the competitive model; this adaptation comes at the price of assuming further restrictions on the preference vectors. Specifically, in addition to assuming the existence of a big gap between two consecutive singular values of the preference matrix (which is inherent to the SVD technique), the algorithm of [6] requires that the preference vectors of users belonging to different types are nearly orthogonal, and that the allowed noise is tiny: each preference vector is obtained by its corresponding canonical vector plus a random noise, which is a vector of  $m$  independent random variables with 0 mean and  $O(1/(m+n))$  variance. Recently, it has been shown that the problem of finding a good object for each user can be solved by very simple combinatorial algorithms without any restriction on the preference vectors [4]: for any set  $P$  of users with a common object they all like, only  $O(m+n \log |P|)$  probes are required overall until all users in  $P$  will find a good object (w.h.p.). The result closest to our work is [3], where algorithms are given for the case where many users have identical preference vectors (see Section 3.1). We note that when the preference matrix is arbitrary, the case where user preferences may be concentrated in sets of positive diameter is much harder than dealing with sets of diameter 0.

**Non-interactive model.** The effectiveness of provable algorithms in the non-interactive model relies on the (usually, implicit) assumption that most user preference vectors can be approximated by a low-rank matrix; basically, this assumption means that there are a few (say, constant) “canonical” preference vectors such that most user preference vectors are linear combinations of the canonical vectors. Under this assumption, algebraic or clustering

techniques can reconstruct most preference vectors with relatively few errors, based on the scarce available data.

Specifically, there are systems that use principal component analysis [7] or singular value decomposition (SVD) [15]. Papadimitriou et al. [14], and Azar et al. [5] rigorously prove conditions under which SVD is effective. It turns out that SVD works well when there exists a very significant gap between the  $k$ th and the  $(k + 1)$ st largest singular values, where  $k$  is the number of canonical vectors in the underlying generative model.

Other generative processes that were considered in the passive model include simple Markov chain models [12, 11], where users randomly select their “type,” and each type is a probability distribution over the objects.

Worst-case (non-stochastic) input is considered in the works by Goldman et al. [8], [9] where, the algorithm is requested to learn a relation represented as a 0/1 matrix. In a basic step, the algorithm must *predict* the value of an entry in the matrix; then that entry is revealed, and the algorithm is charged one unit if the prediction was wrong. By contrast, our model we require that prediction becomes perfect after small number number of errors.

Our model charges one unit every time a grade is revealed; moreover, a prediction algorithm gets to know the true answer regardless of whether the prediction is correct, while in our model, most estimate are never exposed. Assuming random sampling pattern and this (much weaker) performance measure, the algorithms in [8], [9] still suffer from *polynomial* overhead (which might be best possible under the circumstances) even in the simple “noise-free” case where all the players in a large (constant fraction) community are identical.

### 3. The High-Level Algorithm and Basic Building Blocks

**Simplifying assumptions and notation.** Throughout the description of the algorithm, we shall consider a set  $P^*$  of players with “similar taste.” Formally, we assume that there are two parameters  $\frac{\log n}{n} \leq \alpha \leq 1$  and  $D \geq 0$ , such that  $|P^*| \geq \alpha n$   $D(P^*) \leq D$ .  $P^*$  is called an  $(\alpha, D)$ -*typical set*, and its members are  $(\alpha, D)$ -*typical players*, or just *typical*, when  $\alpha$  and  $D$  are clear from the context. In general, there may be multiple, overlapping typical sets of typical players.

For the most part, we describe an algorithm that works with known  $\alpha$  and  $D$ . This assumption is lifted in Section 6. To simplify the description, we also assume, without loss of generality, that  $m = \Theta(n)$  (if  $m < n$  we can add dummy objects, and when  $m > n$  we can let each real player simulate  $\lceil n/m \rceil$  players of the algorithm.) If the assumption that  $\frac{\log n}{n} \leq \alpha$  does not hold then the player is better off by just probing all objects on his own.

**The main algorithm.** Our solution consists of three algorithms, depending on value of  $D$ , as specified in Fig. 1. Algorithms ZERO\_RADIUS, SMALL\_RADIUS and LARGE\_RADIUS are specified in Sections 3.1, 4 and 5, resp.

- (1) If  $D = 0$  apply procedure ZERO\_RADIUS with all players and all objects, using known  $\alpha$ .
- (2) If  $D = O(\log n)$  apply procedure SMALL\_RADIUS with all players and all objects, using known  $\alpha$ .
- (3) Otherwise (i.e.,  $D \geq \Omega(\log n)$ ), apply procedure LARGE\_RADIUS, using known  $\alpha$  and  $D$ .

**Figure 1: Main algorithm for known  $\alpha$  and  $D$  (see Section 6).**

#### 3.1 Exact types solution: Algorithm ZERO\_RADIUS

Below we present, for completeness, an algorithm for the special case of  $D = 0$ , i.e., the case where typical players completely agree on all coordinates. This task is carried out by Algorithm ZERO\_RADIUS. The algorithm, presented in Figure 2, is a slight generalization of an algorithm given in [3]. In the variant we use here, the algorithm uses an abstract **Probe** subroutine that, when invoked by a player  $p \in P$  on an object  $o \in O$ , returns the value of  $o$  for  $p$ . Another slight generalization is that the set of allowed values for an object is not necessarily binary. We explain later how **Probe** is implemented.

- (1) If  $\min(|P|, |O|) < \frac{8c \ln n}{\alpha}$  then invoke **Probe** for all objects in  $O$ , output their values, and return.
- (2) (Otherwise) Partition randomly  $P = P' \cup P''$  and  $O = O' \cup O''$ . Let  $P'$  be the half that contains  $p$ , and let  $P''$  be the other half.
- (3) Recursively execute ZERO\_RADIUS( $P', O'$ ). (Upon returning, values for all objects in  $O'$  were output by all players in  $P'$ , and values for all objects in  $O''$  were output by all players in  $P''$ .)
- (4) Scan the billboard. Let  $V$  be a set of vectors for  $O''$  such that each vector in  $V$  is voted for by at least  $\alpha/2$  fraction of the players in  $P''$ . Compute **SELECT** on  $V$  with distance bound 0. Output the result vector for all objects in  $O''$  and return.

**Figure 2: Algorithm ZERO\_RADIUS executed by player  $p$ .  $P$  is the set of players and  $O$  is the set of objects.**

For this algorithm, and using Theorem 3.2, we have the following result (cf. [3]).

**THEOREM 3.1.** *Suppose that there are at least  $\alpha n$  players with identical value vectors, and that they all run Algorithm ZERO\_RADIUS. Then with probability  $1 - n^{-\Omega(1)}$  all of them output the correct vector, after  $O(\frac{\log n}{\alpha})$  rounds of executing procedure **Probe** (as usual  $m \geq n$ ).*

**Proof Sketch:** (adapted from [3].) Let  $P_T$  denote the set of players with identical preference vectors. By Chernoff (c.f., e.g., [2], Appendix A), in each invocation of ZERO\_RADIUS with  $|P| \geq \frac{8c \ln n}{\alpha}$ , we have, with probability at least  $1 - n^{-\Omega(1)}$ , that  $|P \cap P_T| \geq \alpha|P|/2$ .

Therefore, the correctness of the output follows from induction on the level of recursion and the correctness of Algorithm SELECT. To bound the cost, we note that Step 1 is executed at most once by each player, and its cost is  $O\left(\frac{m \log n}{\alpha^n}\right)$  invocations of **Probe** per player. Each other recursive call of ZERO\_RADIUS entails a call to SELECT with  $O(1/\alpha)$  candidate vectors and distance bound 0, for a total cost of  $O(1/\alpha)$  invocations of **Probe** by Theorem 3.2. Since the depth of the recursion is  $\log\left(\frac{n}{8c \ln n/\alpha}\right) = O(\log n)$ , we have that the total number of invocations of **Probe** done in Step 4 by each player, throughout the execution of the algorithm, is  $O\left(\frac{\log n}{\alpha}\right)$ . ■

### 3.2 The Choose\_Closest problem: Algorithm SELECT

In Algorithm ZERO\_RADIUS and in many other places we use an algorithm solving a problem which can be formulated as follows.

DEFINITION 3.1 (PROBLEM Choose\_Closest).

- **Input:** a set  $V$  of  $k$  vectors and a player  $p$  with preference vector  $v(p)$ .
- **Output:** a vector  $w^* \in V$  such that  $\text{dist}(w^*, v(p)) \leq \text{dist}(w, v(p))$  for all  $w \in V$ .

The algorithm we describe below requires an additional input parameter:

- **Additional input:** A distance bound  $D \geq 0$  such that for some  $w \in V$ ,  $\text{dist}(w, v(p)) \leq D$ .

Given  $D$ , this task can easily be implemented by player  $p$  at the cost of probing  $k(2D + 1)$  coordinates; we present a slightly more efficient algorithm in Figure 3. The algorithm uses the following notation.

NOTATION 3.2. For given vectors  $v, u \in \{0, 1, \star\}^m$ ,  $\tilde{d}(u, v)$  denotes the number of differing coordinates in which both  $u$  and  $v$  have entries that are not  $\star$ .  $\tilde{d}_I(v, u) \stackrel{\text{def}}{=} \tilde{d}(v|_I, u|_I)$  is the restriction of  $\tilde{d}$  to the coordinate set  $I$ .

The algorithm uses the abstract **Probe** action. Its properties are summarized in the following theorem.

THEOREM 3.2. If  $V$  contains a vector at distance at most  $D$  from  $v(p)$ , then Procedure SELECT outputs the lexicographically first vector in  $V$  among the vectors closest to  $v(p)$ . Moreover, the total number of times **Probe** is invoked is never more than  $k(D + 1)$ .

**Proof:** Any vector removed from  $V$  in Step 1c is at distance more than  $D$  from  $v(p)$ . Among the vectors remaining in  $V$  in Step 2, all distinguishing coordinates were probed, so their distances from  $v(p)$  are precisely computed, up to a common additive term. Therefore, the output made in Step 2 is trivially correct by assumption that the closest vector is at distance at most  $D$ . To bound the total number of probes in SELECT, consider the total number of disagreements between  $v(p)$  and all vectors of

- (1) Repeat
  - (1a) Let  $X(V)$  be set of coordinates on which some two vectors in  $V$  differ.
  - (1b) Execute **Probe** on the first coordinate in  $X$  that has not been probed yet.
  - (1c) Remove from  $V$  any vector with more than  $D$  disagreements with  $v(p)$ .

Until all coordinates in  $X(V)$  are probed or  $X(V)$  is empty.
- (2) Let  $Y$  be the set of coordinates probed by  $p$  throughout the algorithm. Find the set of vectors  $U \subseteq V$  closest to  $v(p)$  on  $Y$ , i.e.,
 
$$U = \left\{ v \in V \mid \forall u \in V : \tilde{d}_Y(v, v(p)) \leq \tilde{d}_Y(u, v(p)) \right\}.$$

Output the lexicographically first vector in  $U$ .

Figure 3: Algorithm SELECT using distance bound  $D$ , executed by player  $p$ .

the input set  $V$ . By definition of  $X$ , each probe exposes at least one such disagreement. Since no vector remains in  $V$  after finding  $D + 1$  coordinates on which it disagrees with  $v(p)$ , we get that the total number of probes is at most  $k(D + 1)$ . ■

**Remark:** To ensure that the result of SELECT is completely defined by its input, we require that SELECT disregards probes done before its execution.

## 4. Algorithm SMALL\_RADIUS

In this section we describe Algorithm SMALL\_RADIUS. We assume that  $\alpha$  and  $D$  are given, and the goal is that all these players will output a vector which differs from their input vector by at most  $O(D)$ . The running time of the algorithm is polynomial in  $D$ , and hence it is suitable only for small  $D$  values (in the main algorithm, Algorithm SMALL\_RADIUS is invoked with  $D = O(\log n)$ ).

The algorithm proceeds by repeating the following process  $K$  times (we always set  $K = O(\log n)$ ): The object set  $O$  is partitioned into  $s = O(D^{3/2})$  random parts denoted  $O_i$ , and all players run Algorithm ZERO\_RADIUS on each  $O_i$  object set (Step 1b). However, Algorithm ZERO\_RADIUS is guaranteed to succeed only if there are sufficiently many players that fully agree. To this end, we show that with constant probability, a random partition of  $O$  will have, in all  $O_i$  parts simultaneously, many (but not all) typical players *fully agreeing*. Therefore, one of the  $K$  independent executions of the exact algorithm will succeed in all parts with probability at least  $1 - 2^{-\Omega(K)}$ . However, in each part there may be many typical players whose preferences are not shared by many others *exactly*, and may therefore have arbitrary results in that part, because Theorem 3.1 does not apply in that case. To solve this problem, in Step 1c we force each player to adopt, for each  $i$ , the closest of the popular vectors in  $O_i$ . Then, in Step 2, each player chooses the closest result among the vectors produced in the  $K$  iterations. Since the typical

- (1) For each  $t \in \{1, \dots, K\}$  do:
  - (1a) Partition  $O$  randomly into  $s = O(D^{3/2})$  disjoint subsets:  $O = O_1 \cup O_2 \cup \dots \cup O_s$ .
  - (1b) For each  $i \in \{1, \dots, s\}$ : all players apply procedure `ZERO_RADIUS` to the objects of  $O_i$  using parameter  $\alpha/5$ ; let  $U_i$  be the set of vectors s.t. each is output by at least  $\alpha n/5$  players.
  - (1c) Each player  $p$  applies procedure `SELECT` to  $U_i$  with distance bound  $D$ , obtaining vector  $u_i(p)$  for each  $i \in \{1, \dots, s\}$ . Let  $u^t(p)$  denote the concatenation of  $u_i(p)$  over all  $i$ .
- (2) Each player  $p$  applies procedure `SELECT` with distance bound  $5D$  to the vectors  $u^1(p), \dots, u^K(p)$  computed in Step 1c and outputs the result  $w(p)$ .

**Figure 4: Algorithm `SMALL_RADIUS`.  $\alpha$  and  $D$  are given,  $K$  is a confidence parameter.**

players differ on the  $O$  objects, they will not all choose the same vector in Step 1c; however, we prove that all their chosen vectors lie within  $O(D)$  distance from each other.

#### 4.1 Analysis of `SMALL_RADIUS`

We now state the properties Algorithm `SMALL_RADIUS`. There are a few points which are not obvious. First, in Step 1b we use Algorithm `ZERO_RADIUS` which is guaranteed to work only if there are at least  $\alpha n/5$  players who completely agree on all objects. It turns out that for  $s = O(D^{3/2})$ , there is a constant probability that all instances of `ZERO_RADIUS` are successful in any given iteration. The following lemma proves this crucial fact in more general terms.

**LEMMA 4.1.** *Let  $V$  be a set of  $M$  binary vectors on a set  $O$  of coordinates, and suppose that  $\text{dist}(v, v') \leq d$  for any  $v, v' \in V$ . Let  $O = O_1 \cup O_2 \cup \dots \cup O_s$  be a random partition of  $O$  into  $s$  pairwise disjoint sets, where each coordinate  $j \in O$  is chosen, randomly and independently, to lie in a uniformly chosen  $O_i$ . Call the partition successful if for every  $i \in \{1, \dots, s\}$  there is a set  $U_i \subseteq V$  of size  $|U_i| \geq M/5$ , and such that  $u|_{O_i} = u'|_{O_i}$  for all  $u, u' \in U_i$ . Then, the probability that the partition is not successful is at most  $\frac{10^3 \cdot 5^5 d^3}{6! s^2}$ . In particular, if  $s \geq 100d^{3/2}$  then this probability is smaller than  $1/2$ .*

**Proof:** Let  $X$  be the random variable whose value is the number of ordered 6-tuples  $(i, v_1, v_2, v_3, v_4, v_5)$ , where  $1 \leq i \leq s, v_1, \dots, v_5 \in V$ , and

$$\text{for each } 1 \leq j < k \leq 5, \text{ the vectors } v_j, v_k \text{ differ on } O_i. \quad (1)$$

For a fixed  $i, 1 \leq i \leq s$ , and for fixed distinct vectors  $v_1, \dots, v_5 \in V$ , the probability that the tuple  $(i, v_1, v_2, \dots, v_5)$  satisfies (1) can be bounded as follows. Note, first, that there are at most  $\binom{5}{2}d = 10d$  coordinates in which some pair of the vectors  $v_j$  differ. In order to satisfy (1),  $O_i$  has to contain at least 3 such coordinates

(as, by the pigeonhole principle, at least two of the vectors will agree on each pair of coordinates). Therefore, the required probability is at most

$$\binom{10d}{3} \frac{1}{s^3} < \frac{10^3 d^3}{6s^3}.$$

By linearity of expectation, the expected value of  $X$  satisfies

$$E(X) \leq sM^5 \cdot \frac{10^3 d^3}{6s^3} = \frac{10^3 M^5 d^3}{6s^2}.$$

On the other hand, if there exists some  $i$  such that no set of  $M/5$  of the vectors completely agree on  $O_i$ , then the number of ordered 5-tuples of vectors  $v_1, \dots, v_5$  such that each pair of them differs on  $O_i$  is at least

$$M \cdot \frac{4M}{5} \cdot \frac{3M}{5} \cdot \frac{2M}{5} \cdot \frac{M}{5} = \frac{4! M^5}{5^4}.$$

It follows that if the partition is not successful, then the value of the random variable  $X$  is at least  $\frac{4! M^5}{5^4}$ , and hence, by Markov's Inequality, the probability this happens does not exceed

$$E(X) / \frac{4! M^5}{5^4} \leq \frac{10^3 \cdot 5^5 d^3}{6! s^2}. \quad \blacksquare$$

To deal with our case, let us first introduce the following standard notation.

**NOTATION 4.1.** *Given a vector  $v$  and a subset  $S \subset \mathcal{O}$  of coordinates, let  $v|_S$  denote the projection of  $v$  on  $S$ . Similarly, let  $\text{dist}|_S$  denote the Hamming distance applied to vectors projected on  $S$ .*

Lemma 4.1, applied to our setting with  $M = \alpha n$ , implies the following immediate corollary.

**COROLLARY 4.2.** *For  $s = \Theta(D^{3/2})$ , the following holds with probability at least  $1 - 2^{-\Omega(K)}$  after the execution of Step 1 of Algorithm `SMALL_RADIUS`: there exists an iteration  $t_0 \in \{1, \dots, K\}$  in which for each  $i \in \{1, \dots, s\}$  there exists a set of players  $G_i \subseteq P^*$  satisfying  $|G_i| \geq \alpha n/5$  and  $v(p)|_{O_i} = v(p')|_{O_i}$  for any  $p, p' \in G_i$ .*

By the correctness condition of Algorithm `ZERO_RADIUS`, Corollary 4.2 implies that after Step 1b of Algorithm `SMALL_RADIUS`, w.h.p., there exists an iteration  $t_0$  such that for each  $i \in \{1, \dots, s\}$  there exists a vector  $u_i^{t_0}$  which is identical to the vector of all players in a set  $G_i \subseteq P^*$  with  $|G_i| \geq \alpha n/5$ . However, the  $G_i$ s may be different for each  $i$ . Moreover, note that it is possible to have more than one such  $G_i$  for any given part  $O_i$ . In Step 1c, the algorithm ‘‘stitches’’ a vector  $u^t$  for  $O$  from the  $u_i^t$  components for  $O_i$ . We can now prove that in a successful iteration, *any* vector produced in Step 1c by a typical player is close to *all*  $P^*$  players.

**LEMMA 4.3.** *Consider a partition  $O_1, \dots, O_s$  of  $O$ . Suppose that for each  $i \in \{1, \dots, s\}$  there exists a vector  $u_i$  and a set  $G_i \subseteq P^*$  with  $|G_i| \geq \alpha n/5$  such that  $v(p)|_{O_i} = u_i$  for any  $p \in G_i$ . Let  $u$  be any vector satisfying  $u|_{O_i} = u_i$  for all  $i \in \{1, \dots, s\}$ . Then  $\text{dist}_O(u, v(p)) \leq 5D$  for any player  $p \in P^*$ .*

**Proof:** Fix a value vector  $v^*$  of a player in  $P^*$ . We count the sum of the distances from the vectors of the players in  $P^*$  to  $v^*$  in two different ways. First, by the precondition of Algorithm SMALL\_RADIUS,

$$\sum_{p \in P^*} \text{dist}_O(v(p), v^*) \leq |P^*| \cdot D. \quad (2)$$

On the other hand,

$$\begin{aligned} \sum_{p \in P^*} \text{dist}_O(v(p), v^*) &= \sum_{p \in P^*} \sum_{i=1}^s \text{dist}_{O_i}(v(p), v^*) \\ &\geq \sum_{i=1}^s \sum_{p \in G_i} \text{dist}_{O_i}(u_i, v^*) \\ &\geq \sum_{i=1}^s \frac{|P^*|}{5} \cdot \text{dist}_{O_i}(u_i, v^*) \\ &= \frac{|P^*|}{5} \cdot \text{dist}_O(u, v^*). \end{aligned} \quad (3)$$

Eqs. (2,3) together imply  $\text{dist}_O(u, v^*) \leq 5D$ .  $\blacksquare$

We summarize the properties of Algorithm SMALL\_RADIUS as follows:

**THEOREM 4.4.** *Suppose that there exists a set  $P^*$  of at least  $\alpha n$  players such that  $\text{dist}(v(p), v(p')) \leq D$  for any  $p, p' \in P^*$ . Let  $w(p)$  be the output vector of player  $p \in P^*$  after running Algorithm SMALL\_RADIUS. Then with probability at least  $1 - 2^{-\Omega(K)}$ ,  $\text{dist}_O(v(p), w(p)) \leq 5D$  for every  $p \in P^*$ . Furthermore, the total number of probing rounds is  $O\left(\frac{K}{\alpha} D^{3/2} (D + \log n)\right)$ .*

**Proof:** By Corollary 4.2, with probability at least  $1 - 2^{-\Omega(k)}$  at least one of the iterations satisfies the premise of Lemma 4.3. Using Theorem 3.2 (correctness of SELECT), the correctness claim follows. Regarding complexity, consider a single iteration of Step 1. In such an iteration, procedure ZERO\_RADIUS is invoked  $s = O(D^{3/2})$  times, each time with all  $n$  users, and the total number of objects over all invocations in an iteration is  $m$ . It follows from Theorem 3.1 that the total number of probing rounds spent in procedure ZERO\_RADIUS throughout a single iteration of Step 1 is  $O\left(\frac{\log n}{\alpha} D^{3/2}\right)$ . In addition, each iteration contains  $s = O(D^{3/2})$  applications of SELECT, each time with a bound  $D$  and at most  $O(1/\alpha)$  candidates, totaling  $O(D^{5/2}/\alpha)$  probes in each iteration. Since Step 2 entails only  $O(KD)$  probes, the overall complexity is dominated by Step 1.  $\blacksquare$

## 5. Algorithm LARGE\_RADIUS

In this section we assume that  $\alpha$  and  $D$  are known. Algorithm LARGE\_RADIUS, presented in Figure 5, deals with the case of  $D > \log n$ , and it uses, as subroutines, Algorithms ZERO\_RADIUS and SMALL\_RADIUS.

The algorithm starts (in Step 1) by randomly chopping the object set into small parts denoted  $O_\ell$  and the player set into corresponding parts denoted  $P_\ell$ . The number of parts is such that w.h.p., the distance between any two  $(\alpha, D)$ -typical players on the objects of  $O_\ell$  is bounded

- (1) Partition randomly the objects into  $cD/\log n$  disjoint subsets  $O_\ell$  for  $1 \leq \ell \leq cD/\log n$ . The partition is done by assigning each object independently and uniformly to one of the object subsets. Assign randomly the players to  $cD/\log n$  subsets  $P_\ell$  for  $1 \leq \ell \leq cD/\log n$ . Each player is assigned to  $\lceil \frac{D}{\alpha n} \rceil$  subsets.
- (2) For each  $\ell \in \{1, \dots, cD/\log n\}$ , the players of  $P_\ell$  apply procedure SMALL\_RADIUS to objects  $O_\ell$  with frequency parameter  $\alpha/2$  and confidence parameter  $K = \log n$ . Let  $v_\ell(p)$  denote the output of a player  $p \in P_\ell$  on  $O_\ell$ .
- (3) All players apply procedure COALESCE to each of the sets of vectors  $\{v_\ell(p) \mid p \in P_\ell\}$  produced in Step 2. The result of this step is, for each  $O_\ell$ , a set  $B_\ell$  of at most  $O(1/\alpha)$  vectors of  $\{0, 1, \star\}^{(m \log n)/(cD)}$ .
- (4) Apply procedure ZERO\_RADIUS with all players, where each “object” for the algorithm is a set  $O_\ell$  of primitive objects (see Step 1), with possible values from the  $B_\ell$  vectors (computed in Step 3).

**Figure 5: Algorithm LARGE\_RADIUS for known  $\alpha, D$**

by  $O(\log n)$ . In Step 2, each player set  $P_\ell$  applies procedure SMALL\_RADIUS to the object set  $O_\ell$ . When procedure SMALL\_RADIUS returns, each player in  $P_\ell$  has a complete output vector for  $O_\ell$ , and, w.h.p., the output vectors of any two  $(\alpha, D)$ -typical players differ in only  $O(\log n)$  coordinates. Relying on this property, in Step 3 we aggregate the results for  $O_\ell$  using a basic clustering algorithm called COALESCE. The outcome of the clustering, for each object set  $O_\ell$ , is a collection  $B_\ell$  of only  $O(1/\alpha)$  possible value vectors (“candidates”), such that for each  $\ell$ , there is exactly one candidate which is the closest to *all* typical players on  $O_\ell$ . This key property allows us to apply Algorithm ZERO\_RADIUS in Step 4 by all players, where the “objects” are actually complete  $O_\ell$  sets, and the possible values for each such object are the  $B_\ell$  vectors computed in Step 4. (Recall that Algorithm ZERO\_RADIUS uses SELECT to find the “value” of such virtual object.) When the algorithm ends, any two typical players will have the same output vector, which may include up to  $O(\frac{D}{\alpha})$  “don’t care” entries (which may be set to 0).

We first present Algorithm COALESCE (Step 3).

### 5.1 Algorithm COALESCE

The problem we solve here is the following.

**Input:** A multiset  $V$  of  $n$  vectors, each in  $\{0, 1\}^m$ ; a distance parameter  $D$ ; a frequency parameter  $\alpha$ .

**Output:** A set  $U$  of at most  $1/\alpha$  vectors from  $\{0, 1, \star\}^m$ . The requirement is that if there exists a subset  $V_T \subseteq V$  of size at least  $\alpha n$  satisfying  $\text{dist}(v, v') \leq D$  for all  $v, v' \in V_T$ , then there exists a unique vector  $v^* \in U$  such that (1)  $v^*$  is the closest in  $U$  to any vector in  $V_T$ , and (2) the number of  $\star$  coordinates in  $v^*$  is small (specifically at most  $5D/\alpha$ ).

- (1)  $A \leftarrow \emptyset$ .
- (2) While  $V \neq \emptyset$  do
  - (2a) Remove from  $V$  all vectors  $v$  with  $|\text{ball}(v, D)| < \alpha n$ .
  - (2b) Let  $v$  be the lexicographically first vector  $v \in V$ .
  - (2c)  $A \leftarrow A \cup \{v\}$ ;  $V \leftarrow V \setminus \text{ball}(v, D)$ .
- (3) Let  $B \leftarrow A$ .
- (4) While there are two distinct vectors  $v, v' \in B$  with  $\tilde{d}(v, v') \leq 5D$  do:
  - (4a) Define a vector  $v^*$  by  $v, v'$  as follows: If  $v$  and  $v'$  have the same value for an object  $j$ , let the value of  $v^*$  for  $j$  be their common value. If  $v$  and  $v'$  disagree on  $j$ , let the value of  $v^*$  for  $j$  be  $\star$ .
  - (4b)  $B \leftarrow B \setminus \{v, v'\} \cup \{v^*\}$ .
- (5) Output  $B$ .

**Figure 6: Algorithm COALESCE.**

Note that this problem does not involve probing at all and hence in our case, all players have the same input. The algorithm to solve this problem is presented in Figure 6. It uses the notation  $\text{ball}(v, D) \stackrel{\text{def}}{=} \{u \mid \tilde{d}_I(v, u) \leq D\}$  to denote the ball in the distance metric  $\tilde{d}$  which ignores coordinates with  $\star$  entries (see Notation 3.2).

Pseudo code for the algorithm is presented in Figure 6. To analyze it, we use the following concept. For each vector removed from  $B$  in Step 4b (denoted  $v, v'$  in Figure 6), there is a unique vector that is added to  $B$  (denoted  $v^*$  there). Extending this relation transitively in the natural way, we define for each vector  $v \in A$  a vector  $\text{rep}(v)$  that appears in the final output set. Using this concept, we have the following lemmas.

**LEMMA 5.1.** *For any input vector  $v \in V$  and any  $u \in A$ ,  $\tilde{d}(v, \text{rep}(u)) \leq \text{dist}(v, u)$ .*

**Proof:** By definition, the  $\tilde{d}$  measure ignores  $\star$  entries. The lemma follows from the observation that  $u$  and  $\text{rep}(u)$  agree on all coordinates except the  $\star$  coordinates in  $\text{rep}(u)$ . ■

**LEMMA 5.2.** *For any  $v \in V_T$  there exists a vector  $u$  in the output set such that  $\tilde{d}(v, u) \leq 2D$ .*

**Proof:** Observe first that there must be a vector  $v_1 \in A$  such that  $\text{ball}(v_1, D) \cap \text{ball}(v, D) \neq \emptyset$ : otherwise, the vector  $v$  would have been added to  $A$  in Step 2 since by assumption,  $|\text{ball}(v, D)| \geq \alpha n$ . For that vector  $v_1$  we have  $\text{dist}(v_1, v) \leq 2D$  by the triangle inequality. Therefore, by Lemma 5.1,  $\tilde{d}(v, \text{rep}(v_1)) \leq 2D$ . ■

We summarize with the following statement.

**THEOREM 5.3.** *The output of Algorithm COALESCE contains at most  $1/\alpha$  vectors. There is exactly one vector  $v^*$  in the output set which is closest to all vectors of  $V_T$ ,*

*and  $\tilde{d}(v^*, v) \leq 2D$  for any vector  $v \in V_T$ . Moreover, the number of  $\star$  entries in  $v^*$  is at most  $5D/\alpha$ .*

**Proof:** Regarding the size of the output set, note that by Step 2, each vector in  $A$  represents a disjoint set of size at least  $\alpha n$  vectors from a set whose total size is  $n$ , and hence  $B$  starts at Step 3 with size at most  $1/\alpha$ ; the claim about the size follows, since Step 4 may only reduce the size of  $B$ . The distance claim follows from Lemma 5.2. To see uniqueness, suppose that there were vectors  $u, u' \in B$  and  $v, v' \in V_T$  such that  $u$  is the closest to  $v$  and  $u'$  is the closest to  $v'$ . Then by the triangle inequality  $\tilde{d}(u, u') \leq \tilde{d}(u, v) + \tilde{d}(v, v') + \tilde{d}(v', u') \leq 5D$ . But by the stopping condition of the while loop of Step 4,  $\tilde{d}(u, u') \leq 5D$  iff  $u = u'$ . Finally, regarding the number of  $\star$  entries in  $v^*$ , note that Step 4 is performed at most  $|A| \leq 1/\alpha$  times, and each iteration adds at most  $5D \star$  entries. ■

Note that the output of Algorithm COALESCE is deterministic (the order in which vectors are merged in Step 4 is immaterial). Since there is no probing and all players have the same input, all players will have the same output.

## 5.2 Analysis of LARGE\_RADIUS

We summarize the properties of the main algorithm (Fig. 1) in the following theorem.

**THEOREM 5.4.** *Suppose that the algorithm is given  $0 < \alpha \leq 1$  and  $D \geq 0$  such that there exists a set of players  $P^* \subseteq P$  with  $|P^*| \geq \alpha n$  satisfying  $\text{dist}(v(p), v(p')) \leq D$  for any  $p, p' \in P^*$ . Then w.h.p., the output vector  $w(p)$  of each player  $p \in P^*$  satisfies  $\text{dist}(w(p), v(p)) = O(D/\alpha)$ . The number of probes performed by each player throughout the execution of the algorithm is  $O\left(\frac{\log^{7/2} n}{\alpha^2}\right)$  for  $n \geq m$  (for  $n < m$  we lose a factor of  $m/n$ ).*

To prove Theorem 5.4 we first prove the following immediate properties of the random partitions of Step 1.

**LEMMA 5.5.** *With probability at least  $1 - n^{-\Omega(1)}$ , the following properties hold for each  $1 \leq \ell \leq cD/\log n$ :*

- $|O_\ell| = \Theta\left(\frac{m \log n}{D}\right)$ .
- $|P_\ell| = \Omega\left(\frac{\log n}{\alpha}\right)$ .
- $|P_\ell \cap P^*| = \Theta(\alpha |P_\ell|)$ .
- For any two typical players  $p, p' \in P_\ell \cap P^*$ ,  $\text{dist}_{O_\ell}(v(p), v(p')) = O(\log n)$ .

**Proof:** By Chernoff. For the partition of objects, note that the expected size of  $O_\ell$  is  $\frac{m \log n}{cD} = \Omega(\log n)$  since  $D \leq m$  always; for the partition of players, the expected number of players in  $P_\ell$  is  $\frac{n}{cD/\log n} \cdot \left\lceil \frac{D}{\alpha n} \right\rceil = \Omega\left(\frac{\log n}{\alpha}\right)$ . The expected number of typical players in  $P_\ell$  is  $\Omega(\log n)$ , and the expected number of objects in  $O_\ell$  on which any two typical players differ is  $\frac{D}{cD/\log n} = O(\log n)$ . ■

**Proof of Theorem 5.4:** Let  $1 \leq \ell \leq cD/\log n$ . By Lemma 5.5, with probability at least  $1 - n^{-\Omega(1)}$ , there are at least  $\Omega(\alpha |P_\ell|)$  players from  $P^*$  in  $P_\ell$ , and the

distance between any two of them on  $O_\ell$  is at most  $\lambda \stackrel{\text{def}}{=} \min(D, O(\log n))$ . It therefore follows from Theorem 4.4 that with probability at least  $1 - n^{-\Omega(1)}$ , after Step 2 is done,  $\text{dist}(v_\ell(p), v(p)) \leq \lambda$  for any  $p \in P^* \cap P_\ell$ . Next we note that by Theorem 5.3, after executing Step 3, there exists exactly one vector  $v_\ell$  among all  $O(1/\alpha)$  vectors of  $B_\ell$  which is the closest to any player  $p \in P^*$ , and furthermore, that  $\tilde{d}_{O_\ell}(v_\ell, v(p)) \leq O(\log n)$ . This means that the preconditions for Theorem 3.1 hold, and hence, with probability at least  $1 - n^{-\Omega(1)}$ , all players in  $P^*$  will output the vector composed of the  $v_\ell$  components.

Regarding complexity, note that Steps 1 and 3 do not involve any probing. Consider Step 2. Let us consider Algorithm SMALL\_RADIUS in context: denote by  $n'$  and  $m'$  the number of players and objects (respectively) in the invocation of SMALL\_RADIUS. Algorithm SMALL\_RADIUS is invoked with  $n' = O(\log n/\alpha)$  players and  $m' = O(m \log n/D)$  objects in Step 2 of the main algorithm. (We have  $\frac{n'}{m'} \geq \frac{n}{m}$ ). Also, the confidence parameter is  $K = O(\log n)$ , and distance bound is  $D = O(\log n)$ . It follows from Theorem 4.4 that after Step 2 of the main algorithm, the vector  $w(p)$  adopted by a player  $p \in P_\ell$  satisfies  $\text{dist}_{O_\ell}(v(p), w(p)) \leq O(\log n)$ , and that the total number of probing rounds is at most  $O\left(\frac{\log n}{\alpha} \log^{3/2} n \log n\right) = O\left(\frac{\log^{7/2} n}{\alpha}\right)$ . Next, consider Step 4. Algorithm ZERO\_RADIUS is invoked with  $n$  players and  $D/\log n < n$  objects. Since each logical probe of this invocation consists of  $O(1/\alpha)$  primitive probes, we conclude from Theorem 3.1 that the total number of probes per player in this step is  $O\left(\frac{\log n}{\alpha^2}\right)$ . ■

## 6. Coping with unknown distance bound $D$

Our main algorithm (Figure 1) so far required knowing  $D$  for a given  $\alpha$ . We now describe how to extend it to the case of unknown  $\alpha$  and  $D$ . First, note that for any given  $\alpha$  and a player  $p$ , there exists a minimal  $D = D_p(\alpha)$  such that at least an  $\alpha$  fraction of the players are within distance  $D$  from  $p$ . So suppose for now that  $\alpha$  is given and  $D$  is not known. In this case we run  $O(\log n)$  independent versions of the main algorithm (sequentially or in parallel): in the  $i$ th version, it is run with  $D_i = 2^i$ . We also run another version with  $D = 0$ . From all  $O(\log n)$  resulting output vectors  $w(p)$ , we select (using procedure *Choose\_Closest* described in Section 6.1) the vector that appears to be closest to its input vector  $v(p)$  and output it.

The search procedure increases the running time of the algorithm by a logarithmic factor, and decreases the quality of the output by a constant factor, as compared to the algorithm that assumes known  $\alpha$  and  $D$ . Hence the discrepancy in the running times between Theorem 1.1 and Theorem 5.4.

Next we discuss how to choose  $\alpha$ . Clearly, the running time of the algorithm depends on  $1/\alpha$ . Given a bound on the running time of the algorithm (as defined in Theorem 5.4), we can compute the smallest possible  $\alpha$  and run the algorithm with it. Furthermore, using repeated dou-

bling (and paying a constant factor increase in the running time), we can lift of the requirement that the running time is given: in phase  $j$ , we run the algorithm with  $\alpha = 2^{-j}$ . This way we obtain an “anytime algorithm”, i.e., an algorithm whose output quality at any time  $t$  is close to the best possible in  $t$  time units. We omit the straightforward details from this extended abstract.

### 6.1 Solving *Choose\_Closest* without a distance bound

1. For any pair of distinct vectors  $v, v' \in V$  in turn do:
  - (a) Let  $X$  be the set of coordinates on which non- $\star$  values for  $v$  and  $v'$  differ.
  - (b) Probe randomly  $c \log n$  coordinates from  $X$  (if  $|X| < c \log n$ , probe all coordinates in  $X$ ).
  - (c) Declare  $v'$  “loser” if  $2/3$  or more of the probed coordinates agree with  $v$ ; declare  $v$  “loser” if  $2/3$  or more of the probed coordinates agree with  $v'$ ; otherwise none is declared loser.
2. Output any vector with 0 losses.

**Figure 7: Algorithm RSELECT for the *Choose\_Closest* problem.**

We give an alternative algorithm for solving *Choose\_Closest*, which we call below RSELECT. RSELECT solves the same problem as SELECT, with the following important differences outlined below.

In SELECT, a bound  $D$  on the distance of  $v(p)$  to the set is given as input, and the number of probes is linear in  $D$ . In RSELECT, no such bound is given, and the number of probes per input vector is  $O(\log n)$ , irrespective of the distance between the vectors. On the other hand, SELECT is deterministic and guaranteed to produce the closest vector, while RSELECT is randomized, and is only guaranteed to be close to the closest vector.

**THEOREM 6.1.** *Suppose  $D = \min \{ \tilde{d}(v(p), v) \mid v \in V \}$ . With probability at least  $1 - n^{-\Omega(1)}$ , Algorithm RSELECT outputs a vector  $u$  such that  $\tilde{d}(u, v(p)) = O(D)$ . The number of probes executed by RSELECT is  $O(|V|^2 \log n)$ .*

**Proof:** The complexity bound is obvious. For correctness, let  $u_0$  be the vector in  $V$  which is closest to  $v(p)$ . By Chernoff, the probability that  $u_0$  loses against any other vector is  $1 - n^{-\Omega(1)}$ . Therefore there is at least one vector with 0 losses (w.h.p.). Also, if  $\tilde{d}(u', v) \geq cD$  for some  $u' \in V$ , then the probability that  $u'$  is declared a loser against  $u_0$  is also  $1 - n^{-\Omega(1)}$ . Hence only a vector whose distance from  $v(p)$  is at most  $O(D)$  may have 0 losses. The result follows. ■
