Bit-Level Soft-Decision Decoding of Reed–Solomon Codes

Alexander Vardy and Yair Be’ery, Member, IEEE

Abstract—In this paper, we present a Reed–Solomon decoder that makes use of bit-level soft-decision information. A Reed–Solomon generator matrix which possesses a certain inherent structure in GF(2) is derived. This structure enables representation of the code as a union of cosets, each coset being an interleaver derived. This structure makes it possible to use several binary BCH codes as building blocks. Such partition into cosets provides a clue for efficient bit-level soft-decision decoding. Two decoding algorithms are derived. In the development of the first algorithm we assume a memoryless channel, which makes the value of this algorithm more conceptual than practical. The second algorithm, which is obtained as a modification of the first, does account for channel memory and thus accommodates a bursty channel. Both decoding algorithms are in many cases orders of magnitude more efficient than conventional techniques.

I. INTRODUCTION

The practical importance of Reed–Solomon codes is well established (see [1]–[7]). The application of Reed–Solomon codes spans from deep-space communication standard [2]–[4] and over the air teletext broadcast [5] to frequency-hop spread-spectrum systems [6] and optical communication [7]. Hard-algebraic decoding algorithms. Such decoders have been implemented and operate at rates above 120 Mb/s. Soft-decision decoding algorithms, such as Forney’s generalized minimum distance decoding techniques (say, Viterbi decoding based on the conventional Wolf’s trellis [14]). The reduced complexity of our algorithms is due to a certain symmetric structure of the RS generator matrix over GF(2) which is derived in Section II. The bit-level soft-decision decoders utilizing this structure are presented in Section III.

II. STRUCTURE OF THE GENERATOR MATRIX

Let \( R(N, K) \) be the Reed–Solomon code over GF(2\(^m\)) of length \( N = 2^m - 1 \) and dimension \( K \). We assume that \( R \) is used on a binary channel. Hence, the encoder must employ some fixed linear mapping \( \phi: GF(2M)^N \rightarrow GF(2)^N \) to convert a sequence of \( N \) elements of GF(2\(^m\)) into a string of \( mN \) binary digits.\(^1\) Namely, a codeword \( c = (c_0, c_1, \ldots, c_{N-1}) \in R \), \( c \in GF(2^m) \) is transmitted as

\[
\phi(c) = (c_0^1, c_0^2, \ldots, c_0^m, c_1^1, c_1^2, \ldots, c_1^m, \ldots, c_{N-1}^1, c_{N-1}^2, \ldots, c_{N-1}^m)
\]

where \( c_i \in GF(2) \). Now let \( \alpha \) be a primitive element of GF(2\(^m\)) and let \( \alpha^t, \alpha^0, \cdots, \alpha^{N-K-1} \) be the set of zeros of \( R \). Denote by \( R \) the binary BCH code of length \( N = 2^m - 1 \) with zeros at \( \alpha^t, \alpha^{0}, \cdots, \alpha^{N-K-1} \) and their cyclotomic conjugates over GF(2). Let \( \gamma_1, \gamma_2, \cdots, \gamma_m \) be the basis of GF(2\(^m\)) over GF(2) employed for the linear mapping \( \phi \). We define the codes \( \mathcal{A}_1, \mathcal{A}_2, \cdots, \mathcal{A}_m \) as

\[
\mathcal{A}_j = \{ (\gamma_j b_0, \gamma_j b_1, \cdots, \gamma_j b_{N-1}) | b = (b_0, b_1, \cdots, b_{N-1}) \in R \}
\]

for \( j = 1, 2, \cdots, m \) (1)

where \( b \in GF(2) \) and the product \( \gamma_j b \) is in GF(2\(^m\)). It is well known [15] that \( R \) is a subfield subcode of \( \mathcal{A} \) and, hence, the \( m \) codes defined in (1) are also subcodes of \( R \). Therefore if \( \{ v_1, v_2, \cdots, v_m \} \) is a set of \( K \) generators for \( \mathcal{A} \), we may use the set

\[
\bigcup_{j=1}^{m} \{ \phi(v_j), \phi(v_j^2), \cdots, \phi(v_j^m) \}
\]

as the first \( mk \) rows of a binary generator matrix for \( \mathcal{A} \). By rearranging the columns the structure of Fig. 1 is obtained. This proves our basic theorem.

Theorem 1: Let \( B = \{ b_{ij} \} \) be a generator matrix of the binary BCH code of length \( N = 2^m - 1 \), dimension \( k = K \) and designed distance \( d = 2^m - N - K + 1 \). Then there exists a binary generator matrix of \( \mathcal{A} \), \( G = \{ g_{ij} \} \), \( 0 \leq i \leq mN - 1 \), \( 0 \leq j \leq mK - 1 \)

\(^1\) Alternatively, one could start with binary data and discuss grouping to form the Reed–Solomon symbols over GF(2\(^m\)).
Using the foregoing theorem the set of cosets \( \mathcal{B} \) may be written as a union of cosets

\[
\mathcal{B} = \bigcup_{i=0}^{2^n-1} \mathcal{B}_i
\]

such that \( \Delta = m(K-k) \) and \( \mathcal{B}_i = \{ r' + c \mid c \in \mathcal{B} \} \) where \( \mathcal{B} = \mathcal{B}_1 \cup \mathcal{B}_2 \cup \cdots \cup \mathcal{B}_{2^n} \) is a direct sum of the \( m \) cosets defined in (1) and the vectors \( r' \), \( l = 0, 1, \ldots, 2^n - 1 \) are coset representatives for \( \mathcal{B} \) in \( \mathcal{A} \). Note that the conditions (3a) and (3b) rearrange the columns of \( G \) in such a way that the \( m \) bits of each channel symbol are distributed evenly among the \( m \) BCH codes. This property of the generator matrix offers an alternative insight into the burst error correction capability of Reed-Solomon codes, since each given coset of \( \mathcal{A} \) may be viewed as an interleaver. Assume for simplicity that some message vector \( s \) is mapped into the coset corresponding to \( r = 0 \). Then for this message \( s \) employing \( \mathcal{A}(N, K) \) on a binary channel is equivalent to interleaving \( m \) bits to \( m \) - error correcting binary BCH codes of length \( 2^m - 1 \) where \( 2t + 1 = N - K + 1 \). A coset corresponding to \( r \neq 0 \) is also an interleaver which interleaves \( m \) translates of the binary \((N, K, 2t + 1)\) BCH code. Any channel burst of less than \( m(t-1) + 2 \) bits will be distributed evenly among the \( m \) cosets, at most \( t \) bits to a code, and therefore will be successfully corrected by the hard-decision decoder. This conception of the RS code as a union of cosets, each coset being an interleaver, will be extensively used in the next section.

It is noteworthy that Theorem 1 may be straightforwardly generalized so as to apply to any linear code that contains a subfield subcode. If \( m \) is composite we can employ such generalization of Theorem 1 to obtain additional cosets for the binary generator matrix of \( \mathcal{A} \). Let \( m = p_1 p_2 \cdots p_q \) where \( q \geq 2 \) and \( p_1, p_2, \ldots, p_q \) are (not necessarily distinct) primes. Then \( \operatorname{GF}(2) \subset \operatorname{GF}(2^{p_1}) \subset \cdots \subset \operatorname{GF}(2^{p_q}) \). Let \( \mathcal{A}^{(2)} \) be the BCH code of length \( 2^{p_1} - 1 \) and designed distance \( N - K + 1 \) over \( \operatorname{GF}(2^{p_1}) \subset \cdots \subset \operatorname{GF}(2^{p_q}) \). Evidently \( \mathcal{A}^{(2)} \) is a subfield subcode of \( \mathcal{A}^{(2)} \), provided that \( j_2 > j_1 \). Hence, instead of going directly from \( \mathcal{A} \) to \( \mathcal{A}^{(2)} \) we may use the structure of the whole chain of nested BCH codes over nested fields

\[
\mathcal{A} \subset \mathcal{A}^{(1)} \subset \cdots \subset \mathcal{A}^{(q)} = \mathcal{A}.
\]

Applying Theorem 1 successively \( q \) times we obtain the Reed-Solomon generator matrix given in Fig. 2. For a specific example see the binary generator matrix of the \((15, 9)\) RS code supplied in Fig. 3.

III. SOFT-DECISION DECODING

In this section two decoding algorithms are derived. In the development of Algorithm 1, we assume a binary memoryless channel, which greatly simplifies the derivation. This, however, makes the value of Algorithm 1 more conceptual than practical as this algorithm does not provide for the well-known burst correction capability of Reed-Solomon codes. The practical value of Algorithm 2, which is obtained as a modification of Algorithm 1, is apparently much higher since this algorithm does account for channel memory and thus accommodates a bursty channel.

Suppose that using the linear mapping \( \Phi \) a codeword of \( \mathcal{A} \) is transmitted through a binary channel. We assume through-
out a continuous-output, say additive white Gaussian noise (AWGN) channel, characterized by transition probability densities \( f(v) = f(v | j) \), \( j \in GF(2) \), \( v \in \mathbb{Z} \) where \( \mathbb{Z} \) is the real line. In case of a discrete channel with output alphabet \( \mathcal{Y} \), \( f(v) \) should be replaced by transition probabilities \( P_j(u | v) \), \( j \in GF(2) \), \( u \in \mathcal{Y} \). Now let the word \( v = (v_0, v_1, \cdots, v_{N-1}) = (v_0, v_1, \cdots, v_n, v^m, v^m, v^m, \cdots, v^m, v_{N-1}, v_{N-1}) \) be observed at the output. Maximum likelihood decoding consists of finding a codeword \( c \in \mathcal{C} \) that maximizes \( P(u | c) \), that is maximizes the a posteriori probability \( P(c | u) \), provided that \( P(c) \) is the same for all \( c \in \mathcal{C} \). On a memoryless channel one may as well search the maximum of

\[
M(c) = \sum_{i=0}^{N-1} \log f(v_i | c_i).
\]

Using the partition into cosets (4) and interchanging the order of summation we may perform the maximization as follows:

\[
\max_{c \in \mathcal{C}} M(c) = \max_{b_1} \max_{b_2} \cdots \max_{b_m} \sum_{i=0}^{N-1} \log f(v_i | b_i).
\]

It follows from the structure of the generator matrix obtained in Theorem 1 that in a given coset the choice of \( c_i \) for each \( i \) be made independently for each \( j = 1, 2, \cdots, m \). Hence, we may interchange summation over \( j \) with maximization within a coset, i.e.,

\[
\max_{c \in \mathcal{C}} M(c) = \max_{b_j} \sum_{j=1}^{m} \left( \max_{b_1} \cdots \max_{b_{j-1}} \sum_{i=0}^{N-1} \log f(v_i | b_i) \right) + \sum_{j=m+1}^{N-1} \log f(v_i | b_i),
\]

where \( b_j = (b_1, b_2, \cdots, b_m) \) where \( b_j = (b_{j1}, b_{j2}, \cdots, b_{jm}) \) is the computing within the square brackets is just the soft decoding of the inner BCH code \( \mathcal{B} \). This implies the following decoding algorithm.

**Algorithm 1:** For each of the \( 2^k \) cosets \( \mathcal{B}_j \), \( l = 0, 1, \cdots, 2^k-1 \), and for each coset representative \( r = (r_0, r_1, \cdots, r_m, r_{m+1}, \cdots, r_{2m-1}) \), find the \( m \) codewords \( b_1, b_2, \cdots, b_m \) where \( b_j = (b_{j1}, b_{j2}, \cdots, b_{jm}) \) by maximizing

\[
M_j(b_j) = \sum_{i=0}^{N-1} \log f(v_i | b_i) + r_i
\]

with respect to all \( b \in \mathcal{B} \) for \( j = 1, 2, \cdots, m \).

2) Evaluate

\[
M(c) = \sum_{j=0}^{2^k-1} M_j(b_j) = \sum_{j=0}^{2^k-1} \sum_{i=0}^{N-1} \log f(v_i | c_i)
\]

where \( c_j = b_j + r_i \).

Decode the codeword \( \hat{c} \in \mathcal{C} \) that maximizes (9). ■

For decoding the inner BCH code transforms [17], [18], trellises [14], [19] or other efficient methods [16], [20] are available. Let \( \Omega \) be the computational complexity of either of these methods. Then the number of real addition equivalent operations required by the above decoding algorithm is given by

\[
\mathcal{M}_1 = (m \Omega + m) \cdot 2^m = m \Omega + 1 \cdot 2^{m(K-k)}.
\]

Evidently [17], \( \Omega \) is upper bounded by \( k \cdot 2^k \). However, in most cases \( \Omega \) is much less than that due mainly to a precomputation stage which is common to all the cosets. For instance for the (7, 4, 3) binary Hamming code \( \Omega = 14 \) without precomputation, and \( \Omega = 3 \) if a precomputation stage of 86 real operations is employed (for details see [20]).

A well-known soft-decision decoding technique is the Viterbi algorithm based on the conventional Wolf's trellis [14]. The complexity of this technique when applied to RS code is given [17] by

\[
W = (3m(2K - 2m + 1) + 5) \cdot 2^{m(3m - K - 1)}. \tag{11}
\]

Let us compare the exponents in (10) and (11) for the case of high-rate RS codes. Define \( \rho = (2m - 1) - K \), the redundancy of \( \mathcal{B} \). If \( \rho < \sqrt{2m} \) and \( \rho \) is even then the redundancy of \( \mathcal{C} \) is \( m \rho / 2 \). Hence, \( k = (2m - 1) - m \rho / 2 \), and therefore

\[
m(K - k) = m \cdot \left( 2m - 1 - m \rho \right) = \left( m - \frac{2}{2} \right) \cdot m(2m - K - 1).
\]

Thus for high-rate RS codes the exponent of (10) is less than or equal to the exponent of (11) for \( m = 3, 4 \); whereas for \( m \geq 5 \) the exponent of (11) is lower than that of (10).

For half-rate RS codes and also for some RS codes of slightly higher rate (e.g., \( \mathcal{B}(15, 9), \mathcal{B}(31, 17), \mathcal{B}(31, 21) \), etc.) the situation is different. It may be easily verified that for these codes \( m(K - K) \) is lower than \( m(2m - K - 1) \) for any \( m = 3, 4, 5 \). Obviously, the computational gain would be even greater for extended and doubly extended RS codes.

Finally, the exponent in (10) may be further reduced by means of a recursive algorithm based on the "recursive" structure of the generator matrix derived in Fig. 2. The recursive algorithm, which is derived below, is in some cases considerably more efficient than the existing decoding techniques even for quite high-rate RS codes. Let \( k_j, j = 1, 2, \cdots, q \) denote the dimension of \( \mathcal{B}(j) \) (to keep the notation rigorous we also define \( \mathcal{B}^{(0)} = \mathcal{C} \) and \( k_0 = k \)). The main idea of recursive algorithm is representing each \( \mathcal{B}(j) \subset \mathcal{C} \) as a union of cosets in a way analogous to (4)

\[
\mathcal{B}^{(j)} = \bigcup_{l=0}^{N-j-1} \mathcal{B}^{(j-l)},
\]

such that \( \Delta_j = \Pi_{l=1}^{j} \Delta_j(k_j - k_{j-1}) \) and \( \mathcal{B}^{(j)} = \{ r^j + c \ | \ c \in \mathcal{B}^{(j)} \} \) where

\[
\mathcal{B}^{(j)} = \mathcal{B}^{(j-l)} \oplus \mathcal{B}^{(j-2)} \oplus \cdots \oplus \mathcal{B}^{(j-1)}
\]

and the vectors \( r^j, l = 0, 1, \cdots, 2^j-1 \) are coset representatives for \( \mathcal{B}^{(j)} \) in \( \mathcal{B}^{(j)} \). Given this recursive partition into cosets we may apply Algorithm 1 recursively with \( \mathcal{B} \) and \( \mathcal{B}^{(j)} \) replaced by, respectively, \( \mathcal{B}^{(j+1)} \) and \( \mathcal{B}^{(j)} \) at each stage of recursion. The complexity of such recursive decoding is upper bounded by

\[
\mathcal{M}_2 = (m \Omega + q) \cdot 2^{q(2^{j} + 2j + 1)}.
\]

The primary advantage of the recursive algorithm is that \( \mathcal{C}^{(j)} \) is obviously strictly less than \( \Delta_j \). Thus, for instance, for the (15, 11) RS code over GF(2^4) we have \( \sum_{j=0}^{15} \Delta_j = p_1(k_1 - k) + \sum_{j=0}^{15} p_2(K - k) = 2(9 - 7) + 2 \cdot 2(11 - 9) = 12 \) and \( \Delta = m(K - k) = 16 \); and for the (15, 9) RS code \( \sum_{j=0}^{15} \Delta_j = 14 \) and \( \Delta = 16 \).

As the proposed decoders maximizing the sum of bit and not symbol likelihoods they do not necessarily provide for the inherent burst error correction capability of Reed-Solomon codes. This, as we have already mentioned, is a direct consequence of our initial assumption of a binary memoryless channel. However, with only a slight modification Algorithm 1
becomes suitable for a "bursty" channel as well. We shall refer to the modified version as Algorithm 2. Assuming as in [10], [11], [21], independent noise on each transmitted symbol we may characterize a general binary channel with memory by the 2^n transition probability densities
\[ f(u|x) = f(u_1, u_2, \ldots, u^n|x_1, x_2, \ldots, x^n) \] (13)
where \( x \in \text{GF}(2^n) \) and \( (x_1, x_2, \ldots, x^n) \) is a radius-2 expansion of \( x \). A binary AWGN channel with bursts may be viewed as a special case of (13). Now recall that each coset of \( \mathcal{A} \) is an interleaver. It is well known [22], [23] that interleaving converts a channel with memory (especially a channel with bursts) to one that can be treated as memoryless. Hence, within a given coset of \( \mathcal{A} \) the maximization may be still performed separately for each of the \( m \) interleaved codes and the first step of Algorithm 2 is identical to that of Algorithm 1. However, at step 2 of the modified algorithm, we take into account channel memory by evaluating
\[ M(c) = \sum_{i=0}^{N-1} \log f(u_i/c_i) = \sum_{i=0}^{N-1} \log f(u_1, u_2, \ldots, u^n/b_i^t + r_i^t) \]
and decoding to the codeword \( \hat{c} \) in \( \mathcal{A} \) that maximizes (14). Evidently the above modification almost does not affect the decoding complexity, viz. the number of real operations required by Algorithm 2 is given by
\[ \hat{c} = \left[ m\Omega + 2^m - 1 \right] \cdot 2^{m(K-k)}. \] (15)

**Examples:** In the following examples, we compare the complexities of Algorithm 2 and the conventional trellis decoding. For the (7,5) RS code over GF(2^3) we have \( K = 7 \), \( k = 5 \) and \( \Omega = 3 \) with a precomputation stage of 66 real operations. Hence \( A_4 = 128 \) and the total complexity of soft-decision decoding is 194 real addition-equivalent operations per codeword or about 13 operations per information bit. Decoding the same code with Viterbi algorithm based on Wolf’s trellis requires \( W = 2048 \) real operations per codeword, whereas straightforward maximization requires about 230 000 operations. For the extended (8,5) RS code we have \( A_5 = 136 \) and the total complexity of soft decoding is 208 real operations per codeword or 14 operations per information bit as compared to \( W = 11 376 \) operations per codeword or 758 operations per information bit. For the (15,13), (15,11) and (15,9) RS codes over GF(2^4) we need approximately 90, 800, and 2000 real operations per information bit, respectively. The same numbers using trellis decoding are, respectively, 670, 132 000 and 19 000 000 operations per information bit. The soft-decoding complexity per information bit is plotted versus the asymptotic soft-decision decoding gain \( 10 \log (K/N) \cdot (N - K + 1) \) in Fig. 4.

As illustrated by the foregoing examples the proposed algorithms are in many cases several orders of magnitude more efficient than the existing optimal techniques. In addition the structure regularity of our decoders makes them much more suitable for VLSI implementation than the conventional trellis decoding. Nevertheless, the algorithms presented herein are practically applicable only to small RS codes. Hence this paper should be viewed as just the first step towards the implementation of maximum-likelihood Reed-Solomon decoders that make full use of bit soft-decision information. However, the structure of the RS generator matrix that is derived in Section II may serve a basis for further research into, possibly suboptimal, bit level soft decoding algorithms which would be practically applicable to long RS codes.
