**ABSTRACT.** It is widely believed that the Internet’s AS-graph degree distribution obeys a power-law form. However, it was recently argued that since Internet data is collected in a tree-like fashion, it only produces a sample of the degree distribution, and this sample may be biased. This argument was backed by simulation data and mathematical analysis, which demonstrated that under certain conditions a tree sampling procedure can produce an artificial power-law in the degree distribution. Thus, although the *observed* degree distribution of the AS-graph follows a power-law, this phenomenon may be an *artifact* of the sampling process. In this work we provide some evidence to the contrary. We show, by analysis and simulation, that when the underlying graph degree distribution obeys a power-law with an exponent  $\gamma > 2$ , a tree-like sampling process produces a negligible bias in the sampled degree distribution. Furthermore, recent data collected from the DIMES project, which is not based on single source sampling, indicates that the Internet indeed obeys a power-law degree distribution with an exponent  $\gamma > 2$ . Combining this empirical data with our simulation of `traceroute` experiments on DIMES-measured AS-graph as the *underlying graph*, and with our analysis, we conclude that the bias in the degree distribution calculated from BGP data is negligible.

**1. Introduction.** The connectivity of the Internet crucially depends on the relationships between thousands of Autonomous Systems (ASes) that exchange routing information using the Border Gateway Protocol (BGP). These relationships can be modeled as a graph, called the AS-graph, in which the vertices model the ASes, and the edges model the peering arrangements between the ASes.

Significant progress has been made in the study of the topology of the Internet at the Autonomous Systems (AS) and router levels over the last few years. Numerous studies [17, 23, 2, 12, 20, 31, 32, 11, 4, 3, 19, 27, 21, 8, 6, 25, 29, 28, 18, 10] have ventured to capture the Internet’s topology. Based on these and other topological studies, it is widely believed that the Internet’s degree distribution, in both the AS and router levels, has a power-law form with an exponent  $2 < \gamma < 3$ , i.e., the fraction of vertices with degree  $k$  is proportional to  $k^{-\gamma}$ . Some of these studies are based on data from sources such as RouteViews [26] and CIDR Reports [7].

**1.1. Related work.** It was recently argued [20, 13, 24, 1, 27, 12, 28, 31] that the evidence obtained from the analysis of the Internet graphs sampled as described above may be biased. In a thought-provoking article, Lakhina et al. [20] claimed that a power-law degree distribution may be an artifact of the BGP data collection procedure. They suggest that although the *observed* degree distribution of the AS-graph follows a power-law distribution, the degree distribution of the real AS-graph might be completely different. They claim that with tree-like sampling, such as that employed by `traceroute`, an edge is much more likely to be visible, i.e., included in the sampled graph, if it is close to the root. Moreover, in tree-like sampling, high-degree vertices are more likely to be encountered early on, and therefore they are sampled more accurately than low-degree vertices. They backed this argument with simulations that indicated that under some conditions, a BFS [Breadth First Search] tree sampling process *in itself* is sufficient to produce a power-law degree distribution in the sample, even when the underlying graph is a sufficiently-dense Erdős-Renyi [16] graph.

Subsequently, Clauset and Moore [13] gave a mathematical foundation to the argument of [20]. They showed that BFS tree sampling produces a power-law degree distribution, with an exponent of  $\gamma = 1$ , both for Poisson-distributed random graphs and for  $\delta$ -regular random graphs with high (average) degree. That is, a tree sampling process may have a significant bias, and may produce an artificial power-law—albeit with an exponent that is very different from that observed in the Internet. Moreover, in [13] they claim that one must use a number of sources which grows linearly in the mean degree of the underlying graph in order to accurately estimate the exponent of a graph with a power-law degree distribution.

On the other hand, Petermann and De Los Rios [24] showed that for the exponent obtained for single-source tree sampling of a Barabási-Albert (BA) graph [5] is only slightly under-estimated. This cannot be viewed as strong evidence against the argument of [20], since the analysis assumes a BA-model, which is a highly idealized evolution model of the AS-graph. However, this result does indicate that at least in some power-law graphs, a tree sample does not create a significant bias in the degree distribution.

More recently, Dall’Asta et al. [14, 15, 30] showed that the edge and vertex detection probability depends on the betweenness centrality distribution of the underlying network. They conclude that shortest path sampling provides a better characterization of underlying graphs with a broad distribution of connectivity; the heavier the tail — the higher the statistical accuracy of the sampled graph. Thus in graphs with heavy-tails, such as scale-free networks, the main topological features are therefore discriminated since the relevant statistical information is encapsulated in the degree distribution tail. However, this may not hold for the sampling of homogeneous graphs. Thus they claim that it is very unlikely that the heavy-tailed degree distribution observed in the AS-graph is just an artifact of the mapping strategies.

Achlioptas et al. [1] analyzed the degree distribution discovered by a BFS tree sampling process over a general graph. Among other results, they gave a general, but rather unwieldy, expression of the degree distribution of the sampled graph, depending on the underlying graph degree distribution. This work is the starting point of our analysis: we use the results of [1] to analyze the sampled degree distribution when the underlying graph has a power-law degree distribution.

A new development in the empirical measurement of the Internet topology was suggested recently by Shavitt and Shir [27]. In this work they describe an Internet mapping system called DIMES, a distributed measurement infrastructure for the Internet based on the deployment of thousands of measurement agents around the globe. Unlike BGP data, that is sampled in a tree-like fashion, DIMES executes *traceroutes* among all pairs of its agents, collects the router-level results, and aggregates the AS-graph from this data. Because of this measurement methodology, DIMES discovers significantly more links than BGP-based systems. The salient point for our purposes is that DIMES data too shows a power-law degree distribution, with an exponent  $2 < \gamma < 3$  — and since the DIMES system uses an all-pairs measurement paradigm, it is difficult to claim that the power-law is an artifact of a tree-like sampling.

**1.2. Contributions.** Our main contribution is our analysis of the degree distribution observed in the BFS tree sample, when the underlying graph has a power-law distribution with an exponent  $2 < \gamma < 3$ . Under these conditions, we show that the bias in the power-law is negligible, i.e., the degree distribution of the high-degree nodes in the sample also exhibits a power-law, with the same exponent  $\gamma$ . We support our analysis with simulation results using the DIMES-measured AS-graph as the *underlying graph* and simulating *traceroute* experiments on this graph. Putting this result in the context of the Internet topology, we recall the data collected from the DIMES project is not based on BGP-style tree sampling. Nevertheless, DIMES data indicates that the underlying AS-graph indeed obeys a power-law degree distribution with an exponent  $\gamma > 2$ . By combining our simulation of traceroute experiments on DIMES-measured AS-graph as the underlying graph with our analysis, we conclude that the bias in the degree distribution calculated from BGP data is negligible.

**1.3. Organization:** In the next section we give an overview of the results of [1] we rely on. In Section 3 we show our main result, that the bias in the degree distribution of a tree-sampled power-law graph is negligible. In Section 4 we sketch an alternative, more rigorous, analysis of a weaker result, that validates some of the approximations we used in our main result. Section 5 describes the results of our simulations. We conclude with Section 6.

**2. The results of Achlioptas et al. [1].** The proof of our result is based on the model, sampling process, and the main results described in [1]. In this section we give a brief introduction to the main results we need.

Throughout the paper we use  $G = (V, E)$  to denote the underlying graph, and  $n = |V|$  to denote the number vertices.

**Definition 2.1.** We say that  $\{a_j\}$  is a degree distribution of  $G$  if  $G$  contains  $a_j \cdot n$  nodes of degree  $j$ .

In the model in [1], the graph  $G$  is not a given graph but a random graph chosen out of a family of graphs obeying a given degree distribution  $\{a_j\}$ . The basic setting is the configuration model of [9]: for each vertex of degree  $k$  we create  $k$  copies, and then define the edges of the graph according to a uniformly random matching on these copies.

The model in [1] defines a randomized process, that simultaneously produces a random graph  $G$  obeying the degree distribution  $\{a_j\}$ , and a BFS tree  $T$  that represents the sample. Note that for a given graph  $G$ , a BFS algorithm is a deterministic

algorithm, but different outcomes are possible, depending on the order in which outgoing edges are traversed. In [1] model, a random choice determines this order.

The sampling process is thought of taking place in continuous time. However, for technical reasons the authors define a non-standard notion of time, which we denote by a capitalized word (Time). In this model, the BFS sample process starts at Time  $t = 1$  with an empty tree  $T$ . As the sampling process evolves, Time decreases to  $t = 0$ , when the sample tree  $T$  includes all  $n$  nodes (assuming  $G$  is connected).

Before the process starts, for each vertex  $v$  there are  $\deg(v)$  copies of  $v$ . Each copy is given a real-valued *index* chosen uniformly at random from the unit interval  $[0, 1]$ . Namely, vertex  $v$  has  $\deg(v)$  indices, chosen uniformly and independently at random from the unit interval  $[0, 1]$ . At every Time step  $t$  two copies are matched: one copy is a copy of a vertex already discovered, and the other copy is a copy with index  $t$ . Such a matched pair forms an edge of the original graph. According to [1] at Time  $t$  the indices of the unmatched copies are uniformly random in  $[0, t)$ . Let the *maximum index* of a vertex be the maximum of all its copies' indices. Then at any Time  $t$ , the vertices that have not been discovered yet are precisely those whose maximum index is less than  $t$ . An edge will be *visible*, namely, included in the BFS tree, if at the Time its endpoints are matched one of them is a copy of an undiscovered vertex.

Let  $v_t$  be the vertex that has a copy with maximum index  $t$ . Denote by  $P_{vis}(t)$  the probability that *another* edge outgoing from  $v_t$  appears in the BFS tree. Namely,  $v_t$  is the vertex that was discovered at Time  $t$ , and we are interested in the probability that *another* vertex is discovered through  $v_t$ .

Using the expectation of  $P_{vis}(t)$  as approximation the following Theorem is obtained [1]:<sup>1</sup>

**Theorem 2.2.** *Let  $G$  be a connected graph and let  $\{a_j\}$  be a degree distribution that is upper bounded by a power-law with an exponent larger than 2. Let  $\mu = \sum_j j a_j$  be the mean degree of  $G$ . Then it holds that*

$$P_{vis}(t) \approx \frac{1}{\sum_j j a_j t^j} \sum_k k a_k t^k \left( \frac{\sum_j j a_j t^j}{\mu t^2} \right)^k. \quad (1)$$

**3. The degree distribution of the sampled graph.** Our goal in this section is to show that the bias observed in BFS tree sampling regarding the degree distribution of the sampled graph is not significant, when the underlying graph degree distribution obeys a power-law with an exponent  $\gamma > 2$ . We show the above by examining the BFS tree received by the sampling process of [1], described in the previous section. Finding a BFS tree from a single source is an idealization of the `traceroute` data collection process. Thus, if the bias is negligible when using such BFS process, we argue that it is very likely to be negligible when using the more general case of BGP.

Recall that we focus on a BFS process on a random graph  $G$ . Let  $T$  be the BFS tree received by this process. Let  $\deg_T(v)$  denote the degree of node  $v$  in the BFS tree received from the sampled graph. Let  $\deg_G(v)$  denote the degree of node  $v$  in the graph. We say that a vertex  $v$  has a *high-degree* if  $\deg_G(v) \geq 18$ .

<sup>1</sup>In Lemma 3 of [1] there is a requirement that  $a_j = 0$  for  $j < 3$ . This implies that with high probability the graph is connected. However, if we assume that the graph is connected, which is the case we are interested in, this requirement can be relaxed.

We aim to show that if the underlying graph degree distribution obeys a power-law with an exponent  $\gamma$ , where  $2 < \gamma < 3$ , then the degree distribution of the high-degree vertices of the sampled graph also follows a power-law, with the same exponent value. We denote by  $a_k = C \cdot k^{-\gamma}$  the degree distribution, where  $2 < \gamma < 3$  and  $C > 0$  is the constant normalization factor. Let  $\mu$  denote the mean graph degree, i.e.,  $\mu = E[\text{deg}_G(v)] = \sum_j j a_j$ . Note that since the degree distribution is a power-law with an exponent larger than 2,  $\mu$  is finite.

Our starting point is Theorem 2.2 [1]. Our first step is to approximate the following sum, which appears in Equation (1), when the degree distribution is a power-law:

$$\sum_k k a_k t^k = C \sum_k k k^{-\gamma} t^k = C \sum_k k^{1-\gamma} t^k. \quad (2)$$

We use the integral approximation,  $\sum_k k^{1-\gamma} t^k \approx \int_1^\infty x^{1-\gamma} t^x dx$ . Let  $g(t) = \int_1^\infty x^{1-\gamma} t^x dx$ . Then for all  $i \geq 1$  we have that the  $i$ th derivative of  $g(t)$  is  $g^{(i)}(t) = \int_1^\infty x^{1-\gamma} \prod_{j=0}^{i-1} (x-j) t^{x-i} dx$ . We have that  $g(0) = 0$ ,  $g'(0) = 0$  and  $g^{(i)}(0)$  diverges for all  $i \geq 2$ . We also have  $g(1) = \int_1^\infty x^{1-\gamma} dx = \frac{1}{2-\gamma} x^{2-\gamma} \Big|_1^\infty = \frac{1}{\gamma-2}$ . Finally, we have  $g^{(i)}(1) = \infty$  for all  $i \geq 2$ .

We will approximate  $g(t)$  by a polynomial  $f(t) = \sum_\ell b_\ell t^\ell$ . Obviously, no polynomial has  $f^{(i)}(1) = \infty$  for any  $i$ . However, numerical study of the function shows that a polynomial approximation for the range  $[0, 1]$  can be used, with the minimal-degree non-trivial polynomial we can use is the cubic  $f(t) = t^3/(\gamma-2)$  and

$$g(t) = \int_1^\infty x^{1-\gamma} t^x dx \approx \frac{t^3}{\gamma-2}. \quad (3)$$

Numerical study shows that this is indeed a good approximation in most cases.

Using this approximation, it follows (for  $\gamma > 2$ ),

$$\begin{aligned} \mu(\gamma-2) &= (\gamma-2) \sum_k k a_k = (\gamma-2) C \sum_k k k^{-\gamma} \\ &\approx (\gamma-2) C \int_1^\infty x^{1-\gamma} dx = (\gamma-2) C \frac{1}{\gamma-2} = C. \end{aligned} \quad (4)$$

We now show that most of the edges are detected early during in the sampling process, near Time  $t = 1$ . Recall that  $P_{vis}(t)$  is the probability that the vertex discovered at Time  $t$  gives rise to *another* edge in the BFS tree—i.e., not the edge it was detected with. Using Eqs. (1) and (3) we further approximate  $P_{vis}$ .

$$\begin{aligned} P_{vis}(t) &\approx \frac{1}{\sum_j j a_j t^j} \sum_k k a_k t^k \left( \frac{\sum_j j a_j t^j}{\mu t^2} \right)^k \\ &\approx \frac{\gamma-2}{C t^3} \sum_k \frac{C k^{1-\gamma}}{t^k \mu^k} \left( \frac{C t^3}{\gamma-2} \right)^k = \frac{\gamma-2}{t^3} \sum_k k^{1-\gamma} \left( \frac{C t^2}{\mu(\gamma-2)} \right)^k \end{aligned}$$

and by Eq. (4) we have that

$$P_{vis}(t) \approx \frac{\gamma-2}{t^3} \sum_k k^{1-\gamma} t^{2k}. \quad (5)$$

Let  $w = t^2$ . By substituting  $w$  in Eq. (5) we get  $P_{vis}(t) \approx \frac{\gamma-2}{t^3} \sum_k k^{1-\gamma} w^k$ , and using Eq. (3) again we get that

$$P_{vis}(t) \approx \frac{\gamma-2}{t^3} \frac{w^3}{\gamma-2} = \left(\frac{w}{t}\right)^3 = t^3. \tag{6}$$

Note that at Time  $t = 0$  Eq. (6) gives  $P_{vis} \approx 0$ , which is as expected: at the end of the BFS process no new tree-edges are detected. Furthermore, at Time  $t = 1$  we get  $P_{vis} \approx 1$ , again matching our intuition that at the beginning of the BFS process the edges detected very likely to be tree edges. Moreover, observe that most edges are detected at the beginning of the BFS process.

Recall that in the BFS sampling process of [1] each copy of a vertex  $v$  is assigned a Time index  $t \in [0, 1]$  (Section 2). Now let  $\max\text{-index}(v)$  be the maximum index of a vertex  $v$ , where the maximum is taken over all copies of  $v$ , and let  $v$  be a vertex with graph degree  $i$  and  $\max\text{-index}(v) = t$ . We follow the discussion in [1], and neglect the possibility of self-loops and parallel edges involving a vertex  $v$  and its siblings, and ignore the fact that we are choosing without replacement (i.e., that processing each copy slightly changes the number of undetected vertices and the number of unmatched copies). Under these assumptions, the events that each of  $v$ 's siblings give rise to edges that will be detected in the tree are independent, and [1] shows that the number of visible edges is approximately binomially distributed as  $\text{Bin}(i-1, P_{vis}(t))$ . Therefore,

$$E[\text{deg}_T(v) \mid \text{deg}_G(v) = i, \max\text{-index}(v) = t] = (i-1)P_{vis}(t). \tag{7}$$

Thus, using Eq. (5) it holds that

$$E[\text{deg}_T(v) \mid \text{deg}_G(v) = i, \max\text{-index}(v) = t] \approx (i-1)t^3. \tag{8}$$

Let  $v$  be a vertex with graph degree  $i$ . Then, since  $t = \max\text{-index}(v)$  is the maximum of  $i$  independent uniform variables in  $[0, 1]$ , its probability density is  $dt^i/dt = it^{i-1}$ . Therefore, using Eq. (8), we get

$$\begin{aligned} E[\text{deg}_T(v) \mid \text{deg}_G(v) = i] &= \sum_k k \Pr[\text{deg}_T(v) = k \mid \text{deg}_G(v) = i] \\ &= \sum_k k \int_0^1 it^{i-1} \Pr[\text{deg}_T(v) = k \mid \text{deg}_G(v) = i, \max\text{-index}(v) = t] dt \\ &= \int_0^1 it^{i-1} \sum_k k \Pr[\text{deg}_T(v) = k \mid \text{deg}_G(v) = i, \max\text{-index}(v) = t] dt \\ &= \int_0^1 it^{i-1} E[\text{deg}_T(v) \mid \text{deg}_G(v) = i, \max\text{-index}(v) = t] dt \\ &\approx \int_0^1 it^{i-1} (i-1)t^3 dt = i(i-1) \int_0^1 t^{i-1+3} dt = \frac{i(i-1)}{i+3}. \end{aligned} \tag{9}$$

For high-degree nodes  $\frac{i}{i+3} \geq \frac{6}{7}$ , thus we have that  $E[\text{deg}_T(v) \mid \text{deg}_G(v) = i] \geq \frac{6}{7}(i-1)$ . Let  $m = \frac{i(i-1)}{2(i+3)}$ . Recall that the events that each of  $v$ 's copies give rise to a visible edge are approximately independent. Therefore we can use the Chernoff bound (cf. [22]). Let  $E = E[\text{deg}_T(v) \mid \text{deg}_G(v) = i]$ . Then using Eq. (9), we get

$$\begin{aligned} \Pr[\text{deg}_T(v) < m \mid \text{deg}_G(v) = i] &< \Pr[\text{deg}_T(v) < E/2 \mid \text{deg}_G(v) = i] \\ &< e^{-E/8} \approx e^{-\frac{i(i-1)}{8(i+3)}}. \end{aligned} \tag{10}$$

As a result of Eq. (10) we get that for high-degree nodes with finite probability  $1 + \frac{i(i-1)}{2(i+3)} \leq \text{deg}_T(v) \leq i$  where  $i = \text{deg}_G(v)$ . Since for high-degree nodes  $\frac{i(i-1)}{2(i+3)} \geq \frac{6}{7}(i-1)$ , we have that with finite probability  $1 + \frac{3}{7}(i-1) \leq \text{deg}_T(v) \leq i$ . Therefore,  $\text{deg}_T(v) \approx 1 + c(i-1)$ , where  $c$  is a constant s.t  $\frac{3}{7} \leq c \leq 1$ . Thus for a finite fraction of the high-degree nodes

$$\Pr[\text{deg}_T(v) = k] \approx \Pr\left[\text{deg}_G(v) = \frac{k-1}{c} + 1\right] = \left(\frac{k-1}{c} + 1\right)^{-\gamma} \propto k^{-\gamma}. \quad (11)$$

**4. A more rigorous analysis.** Our analysis of the bias, used a somewhat cavalier polynomial approximation. In this section we give an alternative derivation of the conservation of the power law tail behavior without relying on the polynomial approximation of the sum. We use a more rigorous approach, but we show a weaker result—that validates the approximations up to multiplicative constants for large  $k$ .

**Lemma 4.1.** *If  $\gamma > 2$  then  $Ct \leq C \sum_k k^{1-\gamma} t^k \leq \mu$ , for all  $0 \leq t \leq 1$ .*

*Proof.* All summands are positive, so the sum is larger than the first summand. Also the sum is increasing with  $t$  and equals  $\mu$  for  $t = 1$ . □

**Lemma 4.2.**  *$P_{vis}(t) \geq \frac{C^2}{\mu^2}$  for all  $0 \leq t \leq 1$*

*Proof.* Recall that  $a_k = C \cdot k^{-\gamma}$ . Using equation (1) and Lemma 4.1 we further approximate  $P_{vis}$  as follows.

$$\begin{aligned} P_{vis}(t) &\approx \frac{1}{\sum_j j a_j t^j} \sum_k k a_k t^k \left(\frac{\sum_j j a_j t^j}{\mu t^2}\right)^k \\ &\geq \frac{1}{\mu} \sum_k C \cdot k^{1-\gamma} t^k \left(\frac{Ct}{\mu t^2}\right)^k \\ &\geq \frac{C^2}{\mu^2}. \end{aligned} \quad (12)$$

□

**Theorem 4.3.** *For large enough  $k$  there exists  $c_1 > 0$  such that*

$$c_1 k^{1-\lambda} \leq \Pr[\text{deg}_T(v) \geq k] \leq C k^{1-\lambda}$$

*for a random  $v$ .*

*Proof.* The upper value follows immediately from the fact that the visible degree is at most the graph degree. By Lemma 4.2 we have that  $P_{vis}(t) \geq C^2/\mu^2$  for all  $0 \leq t \leq 1$ . Therefore, for a random  $v$  it follows that

$$E[\text{deg}_T(v)] \geq \frac{C^2}{\mu^2} \text{deg}_G(v)$$

and hence,

$$E[\text{deg}_G(v) - \text{deg}_T(v)] \leq \left(1 - \frac{C^2}{\mu^2}\right) \text{deg}_G(v).$$

By the Markov inequality this means that

$$\Pr[\text{deg}_G(v) - \text{deg}_T(v) > \alpha] < \frac{\left(1 - \frac{C^2}{\mu^2}\right) \text{deg}_G(v)}{\alpha}.$$

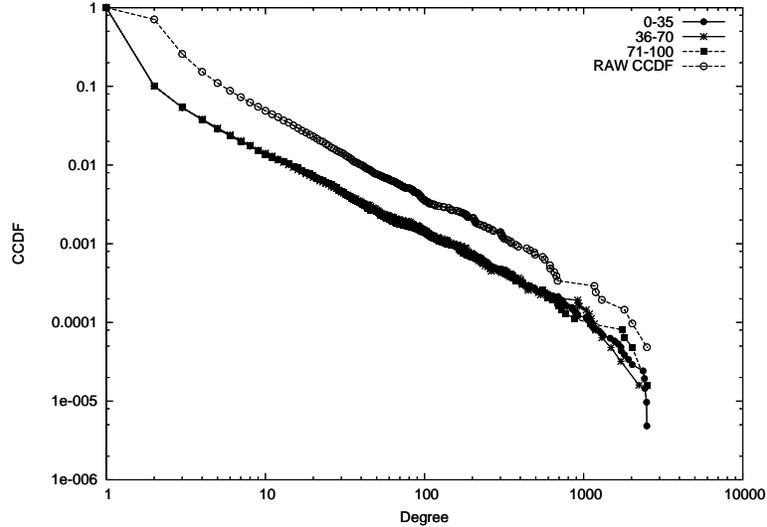

FIGURE 1. CCDF graphs for BFS trees and raw DIMES data

TABLE 1. Sampled power law exponent  $\gamma$  for each group.

Data Source	$\gamma$
Group 1	2.101
Group 2	2.079
Group 3	2.072
Raw DIMES Data	2.126

Take  $\alpha = \left(1 - \frac{C^2}{\mu^2} + \epsilon\right) \deg_G(v)$  for some constant  $\epsilon$ . The probability of a node  $v$  to have such a difference between its tree-degree and its graph-degree is at most some constant less than 1, and therefore, a constant fraction of the nodes have a degree proportional to the original degree. Therefore, the tail of the distribution has a power law with exponent at least  $\gamma$ .  $\square$

Notice that for all  $\gamma' < \gamma$ , there exists some large  $K_*$ , such that  $C'K_*^{\gamma'} > CK_*^\gamma$ . Therefore, the exponent of the power law can not decrease throughout the entire degree sequence.

In fact, since the high degree nodes are discovered almost surely at  $t \approx 1$ , we expect to see  $P_{vis} \approx 1$  for these nodes, and therefore, the behavior of the tail is almost unchanged. Giving an exact bound near  $t = 1$  is deferred to a future work.

**5. Simulation results.** To further validate our analysis, we conducted a simulation study. We used the data collected by Shavitt and Shir [27] in the DIMES project as our underlying graph.

To test whether the choice of the BFS tree root has a noticeable effect on the resulting degree distribution, the graph vertices were split into the following 3 groups, based on their graph degree:

1. Low-degree nodes:  $1 \leq \deg_G(v) < 35$ ,

2. Medium-degree nodes:  $36 \leq \text{deg}_G(v) < 70$ ,
3. High-degree nodes:  $\text{deg}_G(v) \geq 71$ .

From each group we selected 10 nodes at random and constructed a BFS tree for each, where the selected node was a tree root. An average CCDF<sup>2</sup> of degree distribution was then calculated for every group. We compared the resulting curves to the original connectivity data, collected by DIMES.

Figure 1 shows the plotted CCDF curves for the three groups, and the curve for the raw DIMES data. The figure clearly shows the familiar power-law curves in all cases, and we can see that the curves are almost parallel graphs, indicating a similar value of the power-law exponent  $\gamma$ .

Table 1 contains the computed values of  $\gamma$  for each group. We can immediately see that the values of  $\gamma$  on the sampled trees (2.072–2.101) are very close to the true power-law exponent (2.126), thus validating our analysis that the bias is minor. Furthermore, Table 1 shows that the  $\gamma$  values for the three groups are all close to one another, with a minor decrease in value as the degree of the root grows. Thus, it seems that the value of the power-law exponent in the sampled tree is largely invariant to the degree of the tree root.

**6. Conclusions and future work.** We have shown that if the underlying graph degree distribution obeys a power-law with an exponent  $\gamma > 2$  (as is the case in the AS-graph) then with w.h.p the degree distribution of the high-degree vertices of the sampled graph also follows a power-law, with the same exponent value. Therefore, the bias observed in tree-sampling regarding the degree distribution of the sampled graph is not significant under these conditions. Furthermore, since according the non-tree-sampled data of [27] the AS-graph degree distribution *does* obey a power-law with an exponent  $\gamma$  between 2 and 3, we conclude that the bias observed in the degree distribution of the BGP data is negligible. Thus, the commonly held view of the Internet’s topology as having a degree distribution of a power-law form with an exponent  $2 < \gamma < 3$  seems to be correct, and unlikely to be a by-product of the BGP data collection process.

**Acknowledgment.** we thank Sagy Bar for producing the CCDF graphs from the DIMES data.
